LAKE FACTS

Lake Name:	Countryside Lake
Historical Name:	None
Nearest Municipality:	Mundelein
Location:	T44N, R10E, Sections 26,27,34,35
Elevation:	785.0 feet
Major Tributaries:	Indian Creek
Watershed:	Des Plaines River
Sub-watershed:	Indian Creek
Receiving Waterbody:	Des Plaines River
Surface Area:	141.8 acres
Shoreline Length:	3.9 miles
Maximum Depth:	10.0 feet
Average Depth:	6.5 feet
Lake Volume:	921.6 acre-feet
Lake Type:	Impoundment
Watershed Area:	1780.0 acres
Major Watershed Land Uses:	Single Family, Forest and Grassland
Bottom Ownership:	Private
Management Entities:	Countryside Lake Association
Current and Historical Uses:	Fishing, no wake boating, swimming
Description of Access:	No public access

In 2005, Countryside Lake was chosen to be one of seven "sentinel" lakes in the county that the Lakes Management Unit (LMU) will be monitoring annually for five years, beginning with the 2005 season. This report summarizes the water quality sampling results and aquatic plant surveys conducted in 2007 on Countryside Lake. Similar reports have been written on data collected in 2000, 2005, and 2006 and are available from the LMU.

SUMMARY OF WATER QUALITY

Water samples were collected monthly from May through September at the deepest point in the lake (Figure 1; Appendix A). Countryside Lake was sampled at depths of three feet and six feet, and the samples were analyzed for various water quality parameters (Appendix C). In addition, the LMU's beach sampling program has included the Countryside Lake Association (CLA) beach since 1988. In 2007 there were no recommended beach closings.

Countryside Lake was well mixed throughout the season due to the lake being shallow and easily mixed by wind. This mixing was reflected in the dissolved oxygen (DO) concentrations, as well as the other water quality parameters. The concentrations from the epilimnion were similar to the hypolimnion, therefore only the data from the epilimnion will be discussed. DO concentrations of at least 5.0 mg/L were recorded in Countryside Lake in 2007 from the water's surface down to the lake bottom during all months, except August (Appendix B). In August the DO concentration was below 5.0 mg/L at depths greater than eight feet. This was likely due to the decomposition of plants and algae from the monthly chemical treatments. Since a bathymetric map with a morphometric table was not available, it was not possible to calculate the percent of the lake affected by the low DO conditions.

Secchi disk depth (water clarity) averaged 5.38 feet during 2007, which was above the Lake County median of 3.28 feet (Appendix D). This was an increase from the 2006 average of 5.07 feet and the 2005 average of 4.09 feet (Table 1). The water was clear to the bottom in June, so no measurement was able to be taken by the LMU. Countryside Lake has participated in the Illinois Environmental Protection Agency's (IEPA) Volunteer Lake Monitoring Program (VLMP) since 2001. The VLMP Secchi depth averages over the past seven years have been between 2.97 feet and 8.08 feet (Figure 2). The VLMP data in 2007 was only collected during May and June which is why the average is so high. The LMU had high readings in May and June and then saw a decline from July through September. If the VLMP data would have been collected for the entire season, it is expected that the seasonal average would have been similar to that of the LMU. The VLMP data from 2001 through 2007 had an average Secchi depth of 4.53 feet while the LMU data from 2000, 2005, 2006, and 2007 had an average Secchi depth of 4.55 feet. Water clarity is related to the amount of total suspended solids (TSS) concentration in the water column. As the TSS increased, the water clarity decreased (Figure 3). The 2007 average TSS concentration of 4.7 mg/L was a decrease from the 2006 average of 6.7 mg/L, but an increase from the 2005 average of 4.0 mg/L. The 2007 average TSS was below the Lake County median of 8.0 mg/L. The decrease from 2006 could be due to less algae blooms in 2007. The decrease could have been as result of the dry conditions early in the year. These conditions caused no water to flow into the lake from the surrounding watershed. Once the precipitation began in August, the TSS increased and water was noted flowing over the outlet. As part of the monthly sampling, water level was measured at the boat launch near the outlet. The lake level

decreased by 4.6 inches from May through July and then increased 6.8 inches from July to August. The level then dropped 3.5 inches from August to September for a seasonal decrease of 1.4 inches.

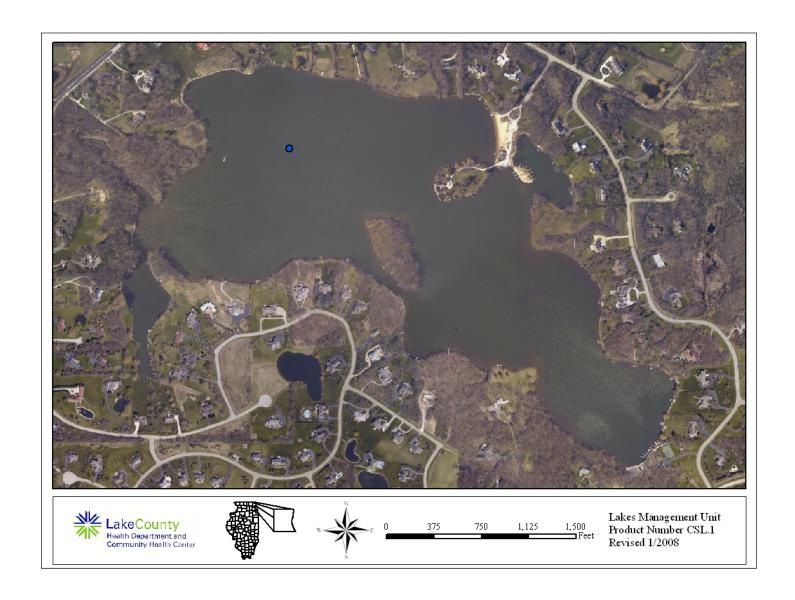

Data collected by the IEPA, LMU, and CLA has shown negative impacts on the Countryside Lake watershed due to runoff from an upstream development. CLA has also been monitoring the lake's turbidity, TP, TSS, and Total organic carbon after significant rain events at six locations around the lake. They continue to see high levels entering the lake from Indian Creek, however not as high as when the land upstream was under development.

Total phosphorous (TP) was relatively consistent throughout the 2007 sampling season and was below the Lake County median of 0.063 mg/L. The average TP concentrations for 2005, 2006, and 2007 were 0.051 mg/L, 0.079 mg/L, and 0.033, respectively. This decrease in TP was likely the result of an increase in plant density from previous years. Aquatic plants consume phosphorous. In addition, there were no inputs from upstream due to the low water levels at the beginning of the summer. In lakes that do not stratify, like Countryside Lake, phosphorus can be released from sediment through biological/mechanical processes or from plants/algae as they die. The trophic state of Countryside Lake, in terms of its phosphorus concentration, from 2005 through 2007 was eutrophic, with TSIp scores of 60.9, 67.1, and 54.7, respectively. Countryside Lake was 40th out of 163 lakes in Lake County (Table 2).

The IEPA has assessment indices to classify Illinois lakes for their ability to support aquatic life and recreational uses. The guidelines consider several aspects, such as water clarity, phosphorus concentrations (for the trophic state index), and aquatic plant coverage. According to this index, Countryside Lake provided *Full* support of aquatic life and recreational activities (such as boating), and provided *Full* overall use in 2007.

The Lake County median conductivity reading for near surface samples was 0.8038 milliSiemens/cm (mS/cm). During 2007, the average conductivity reading for Countryside Lake was lower at 0.6842 mS/cm. This was down from the 2005 and 2006 averages of 0.7546 mS/cm and 0.7196 mS/cm. The 2005 and 2006 averages were likely higher due to the lack of precipitation, which decreased the lake volume and therefore concentrated the Cl⁻. Plus there was minimal "flushing". The 2007 average Cl concentration in Countryside Lake was lower than the Lake County median of 158 mg/L, with a seasonal average of 129 mg/L. This was down from the 2006 average of 133 mg/L and up from the 2005 average of 122 mg/L. When looking at the data on a monthly basis, the conductivity and Cl⁻ concentrations were above the 2006 averages until August and September when the conductivity and Cl concentrations dropped. This drop was due to heavy rains during those months. It was reported that water flowed over the dam which caused the system to be "flushed." Road salt used for winter deicing was the probable source of Cl⁻. The Illinois Environmental Protection Agency (IEPA) standard for chloride is 500 mg/L. Once values exceed this standard, the waterbody is deemed to be impaired, thus impacting aquatic life. A study done in Canada reported 10% of aquatic species were harmed by prolonged exposure to Cl⁻ concentrations greater than 220 mg/L. Additionally, shifts in algal populations were associated with Cl concentrations as low as 12 mg/l. Therefore, it is important to keep the use of road salts to a minimum within the watershed.

SUMMARY OF AQUATIC MACROPHYTES

Aquatic plant (macrophyte) surveys were conducted in May and August of 2007. Sampling sites were based on a grid system created by mapping software (ArcGIS), with each site located 60 meters apart. On Countryside Lake there were 159 sites sampled in May (Figure 4) and 156 sites sampled in August (Figure 5). Plants were found at 106 sites in May and 144 sites in August (Table 3a,b). Overall, a total of four plant species and one macro-algae were found (Table 4). Only a macro-algae (*Chara* spp.) and Curlyleaf Pondweed were found in May, at 21% and 53% of the sampling sites. In August, Curlyleaf Pondweed was found at 78% of the sampling sites and Chara spp. at 45% of the sampling sites. Flatsteam Pondweed, Sago Pondweed, and Southern Naiad were other species found but were less abundant. These aquatic plant densities did not seem to affect the recreational use of Countryside Lake. Diversity was down from 2006 when five aquatic plant species and one macro-algae were found, but up from 2005 when only three aquatic plants species and one macro-algae were found. In 2000 12 aquatic plant species and one macro-algae were present. Countryside Lake was dominated by Curlyleaf Pondweed in May and *Chara* spp. in August during 2000, 2005, 2006, and 2007. During 2007, the 1% light level reached the bottom from May through August. In May, plants were found down to 11.0 feet and in August they were found down to 9.8 feet.

CLA treated the lake with fluridone (Sonar ASTM) at a concentration of 8 ppb on April 10, 2007 (5 gallons) and a bump up to hold concentration on May 3, 2007 (2.5 gallons) to control the aquatic plants. It was also treated weekly with copper sulfate (a season total of 1330+ pounds) to control algae from the end of April through mid-September with the exception of May 16th, June 6th, July11th, and 18th, August 15th, and September 5th. This was a significant decrease in the amount of Copper Sulfate applied in 2006 when a seasonal total of 2005 pounds were applied. Even though there was a decrease, it may not be necessary to apply this much copper sulfate. Therefore, the current aquatic plant management plan should be evaluated for possible changes. This could save money and provide less potential impact to the environment. In addition, during the August aquatic plant survey Water Hyacinth was noticed growing along the west shoreline between two piers. This sighting was brought to the attention of CLA and they had their applicator treat that section of shoreline on August 16th to kill this exotic, invasive plant. During the September sampling all of the Water Hyacinth appeared to be dead. CLA should inform members that the release of any exotic species into natural lakes is strongly discouraged.

Floristic Quality Index (FQI) is a rapid assessment tool designed to evaluate the closeness of the flora of an area to that of undisturbed conditions. It can be used to: 1) identify natural areas, 2) compare the quality of different sites or different locations within a single site, 3) monitor long-term floristic trends, and 4) monitor habitat restoration efforts. A high FQI number indicates that there is a large number of sensitive, high quality plant species present in the lake. Non-native species were also included in the FQI calculations for Lake County lakes. The average FQI for 2000-2007 Lake County lakes was 13.6 (Table 5). Countryside Lake had a FQI of 10.5 in 2007. This was down from 2006 when the FQI was 12.5 and up from 2005 when the FQI was 5.8.

Table 3a. Aquatic plant species found at the 159 sampling sites on Countryside Lake, 2007. Maximum depth that plants were found was feet 11.0.

SUMMARY OF WILDLIFE AND HABITAT

Wildlife observations were made on a monthly basis during water quality and aquatic plant sampling activities. Because the lake is in the middle of a residential setting with the majority of the shoreline riprap, habitat for wildlife was limited. Most of the birds were those common to residential settings (Table 6). There was a healthy population of mature trees providing good habitat for a variety of bird species. A few large, dead trees provided excellent habitat for Double Crested Cormorants, Osprey, and Great Blue Herons. Additionally, there were several shrub areas that provided habitat for smaller bird and mammal species. However, there are several areas in need of habitat improvement on Countryside Lake. Enhancing habitat for terrestrial wildlife such as birds and small mammals can be accomplished through the addition of shoreline buffer zones and is recommended as one aspect of shoreline protection. Erecting birdhouses and allowing brush or trees that have fallen into the water to remain creates additional habitat for birds, fish, reptiles, and amphibians. Countryside Lake also had a substantial population of the exotic Chinese Mystery Snail. Many dead snails were noted near the boat ramp on several occasions throughout the summer.

Countryside Lake has an ongoing fish-stocking program. Fish species that have been stocked include Largemouth Bass, Black Crappie, Bluegill, Northern Pike, Tiger Musky, Walleye, and Yellow Perch.

Table 6. Wildlife species observed on Countryside Lake, May – September 2007.

APPENDIX A. MI	ETHODS FOR FIELI LABORATORY A	ΓΙΟΝ AND

Water Sampling and Laboratory Analyses

Two water samples were collected once a month from May through September. Sample locations were at the deepest point in the lake (see sample site map), three feet below the surface, and 3 feet above the bottom. Samples were collected with a horizontal Van Dorn water sampler. Approximately three liters of water were collected for each sample for all lab analyses. After collection, all samples were placed in a cooler with ice until delivered to the Lake County Health Department lab, where they were refrigerated. Analytical methods for the parameters are listed in Table A1. Except nitrate nitrogen, all methods are from the Eighteenth Edition of Standard Methods, (eds. American Public Health Association, American Water Works Association, and Water Pollution Control Federation, 1992). Methodology for nitrate nitrogen was taken from the 14th edition of Standard Methods. Dissolved oxygen, temperature, conductivity and pH were measured at the deep hole with a Hydrolab DataSonde® 4a. Photosynthetic Active Radiation (PAR) was recorded using a LI-COR® 192 Spherical Sensor attached to the Hydrolab DataSonde® 4a. Readings were taken at the surface and then every two feet until reaching the bottom.

Plant Sampling

In order to randomly sample each lake, mapping software (ArcMap 9.1) overlaid a grid pattern onto a 2006 aerial photo of Lake County and placed points 60 or 30 meters apart, depending on lake size. Plants were sampled using a garden rake fitted with hardware cloth. The hardware cloth surrounded the rake tines and is tapered two feet up the handle. A rope was tied to the end of the handle for retrieval. At designated sampling sites, the rake was tossed into the water, and using the attached rope, was dragged across the bottom, toward the boat. After pulling the rake into the boat, plant coverage was assessed for overall abundance. Then plants were individually identified and placed in categories based on coverage. Plants that were not found on the rake but were seen in the immediate vicinity of the boat at the time of sampling were also recorded. Plants difficult to identify in the field were placed in plastic bags and identified with plant keys after returning to the office. The depth of each sampling location was measured either by a hand-held depth meter, or by pushing the rake straight down and measuring the depth along the rope or rake handle. One-foot increments were marked along the rope and rake handle to aid in depth estimation.

Wildlife Assessment

Species of wildlife were noted during visits to each lake. When possible, wildlife was identified to species by sight or sound. However, due to time constraints, collection of quantitative information was not possible. Thus, all data should be considered anecdotal. Some of the species on the list may have only been seen once, or were spotted during their migration through the area.

Table A1. Analytical methods used for water quality parameters.

Parameter	Method
Temperature	Hydrolab DataSonde® 4a or
	YSI 6600 Sonde®
Dissolved oxygen	Hydrolab DataSonde ®4a or
	YSI 6600 Sonde®
Nitrate and Nitrite nitrogen	USEPA 353.2 rev. 2.0
	EPA-600/R-93/100
	Detection Limit = 0.05 mg/L
Ammonia nitrogen	SM 18 th ed. Electrode method,
	#4500 NH ₃ -F
	Detection Limit = 0.1 mg/L
Total Kjeldahl nitrogen	SM 18 th ed, 4500-N _{org} C
	Semi-Micro Kjeldahl, plus 4500 NH ₃ -F
	Detection Limit = 0.5 mg/L
pН	Hydrolab DataSonde® 4a, or
	YSI 6600 Sonde®
	Electrometric method
Total solids	SM 18 th ed, Method #2540B
Total suspended solids	SM 18 th ed, Method #2540D
	Detection Limit = 0.5 mg/L
Chloride	SM 18 th ed, Method #4500C1-D
Total volatile solids	SM 18 th ed, Method #2540E, from total solids
Alkalinity	SM 18 th ed, Method #2320B,
	patentiometric titration curve method
Conductivity	Hydrolab DataSonde® 4a or
_	YSI 6600 Sonde®
Total phosphorus	SM 18 th ed, Methods #4500-P B 5 and
	#4500-P E
	Detection Limit = 0.01 mg/L
Soluble reactive phosphorus	SM 18 th ed, Methods #4500-P B 1 and
	#4500-P E
	Detection Limit = 0.005 mg/L
Clarity	Secchi disk
Color	Illinois EPA Volunteer Lake
	Monitoring Color Chart
Photosynthetic Active Radiation	Hydrolab DataSonde® 4a or YSI 6600
(PAR)	Sonde®, LI-COR® 192 Spherical
	Sensor

APPENDIX C. INTERPRETING YOUR LAKE'S WATER QUALITY
DATA.

Lakes possess a unique set of physical and chemical characteristics that will change over time. These in-lake water quality characteristics, or parameters, are used to describe and measure the quality of lakes, and they relate to one another in very distinct ways. As a result, it is virtually impossible to change any one component in or around a lake without affecting several other components, and it is important to understand how these components are linked.

The following pages will discuss the different water quality parameters measured by Lake County Health Department staff, how these parameters relate to each other, and why the measurement of each parameter is important. The median values (the middle number of the data set, where half of the numbers have greater values, and half have lesser values) of data collected from Lake County lakes from 2000-2005 will be used in the following discussion.

Temperature and Dissolved Oxygen:

Water temperature fluctuations will occur in response to changes in air temperatures, and can have dramatic impacts on several parameters in the lake. In the spring and fall, lakes tend to have uniform, well-mixed conditions throughout the water column (surface to the lake bottom). However, during the summer, deeper lakes will separate into distinct water layers. As surface water temperatures increase with increasing air temperatures, a large density difference will form between the heated surface water and colder bottom water. Once this difference is large enough, these two water layers will separate and generally will not mix again until the fall. At this time the lake is thermally stratified. The warm upper water layer is called the *epilimnion*, while the cold bottom water layer is called the *hypolimnion*. In some shallow lakes, stratification and destratification can occur several times during the summer. If this occurs the lake is described as polymictic. Thermal stratification also occurs to a lesser extent during the winter, when warmer bottom water becomes separated from ice-forming water at the surface until mixing occurs during spring ice-out.

Monthly temperature profiles were established on each lake by measuring water temperature every foot (lakes < 15 feet deep) or every two feet (lakes > 15 feet deep) from the lake surface to the lake bottom. These profiles are important in understanding the distribution of chemical/biological characteristics and because increasing water temperature and the establishment of thermal stratification have a direct impact on dissolved oxygen (DO) concentrations in the water column. If a lake is shallow and easily mixed by wind, the DO concentration is usually consistent throughout the water column. However, shallow lakes are typically dominated by either plants or algae, and increasing water temperatures during the summer speeds up the rates of photosynthesis and decomposition in surface waters. When many of the plants or algae die at the end of the growing season, their decomposition results in heavy oxygen consumption and can lead to an oxygen crash. In deeper, thermally stratified lakes, oxygen production is greatest in the top portion of the lake, where sunlight drives photosynthesis, and oxygen consumption is greatest near the bottom of a lake, where sunken organic matter accumulates and decomposes. The oxygen difference between the top and bottom water layers can be dramatic, with plenty of oxygen near the surface, but practically none near the bottom. The oxygen profiles measured during the water quality study can illustrate if

this is occurring. This is important because the absence of oxygen (anoxia) near the lake bottom can have adverse effects in eutrophic lakes resulting in the chemical release of phosphorus from lake sediment and the production of hydrogen sulfide (rotten egg smell) and other gases in the bottom waters. Low oxygen conditions in the upper water of a lake can also be problematic since all aquatic organisms need oxygen to live. Some oxygen may be present in the water, but at too low a concentration to sustain aquatic life. Oxygen is needed by all plants, virtually all algae and for many chemical reactions that are important in lake functioning. Most adult sport-fish such as largemouth bass and bluegill require at least 3 mg/L of DO in the water to survive. However, their offspring require at least 5 mg/L DO as they are more sensitive to DO stress. When DO concentrations drop below 3 mg/L, rough fish such as carp and green sunfish are favored and over time will become the dominant fish species.

External pollution in the form of oxygen-demanding organic matter (i.e., sewage, lawn clippings, soil from shoreline erosion, and agricultural runoff) or nutrients that stimulate the growth of excessive organic matter (i.e., algae and plants) can reduce average DO concentrations in the lake by increasing oxygen consumption. This can have a detrimental impact on the fish community, which may be squeezed into a very small volume of water as a result of high temperatures in the epilimnion and low DO levels in the hypolimnion.

Nutrients:

Phosphorus:

For most Lake County lakes, phosphorus is the nutrient that limits plant and algae growth. This means that any addition of phosphorus to a lake will typically result in algae blooms or high plant densities during the summer. The source of phosphorus to a lake can be external or internal (or both). External sources of phosphorus enter a lake through point (i.e., storm pipes and wastewater discharge) and non-point runoff (i.e., overland water flow). This runoff can pick up large amounts of phosphorus from agricultural fields, septic systems or impervious surfaces before it empties into the lake.

Internal sources of phosphorus originate within the lake and are typically linked to the lake sediment. In lakes with high oxygen levels (oxic), phosphorus can be released from the sediment through plants or sediment resuspension. Plants take up sediment-bound phosphorus through their roots, releasing it in small amounts to the water column throughout their life cycles, and in large amounts once they die and begin to decompose. Sediment resuspension can occur through biological or mechanical means. Bottom-feeding fish, such as common carp and black bullhead can release phosphorus by stirring up bottom sediment during feeding activities and can add phosphorus to a lake through their fecal matter. Sediment resuspension, and subsequent phosphorus release, can also occur via wind/wave action or through the use of artificial aerators, especially in shallow lakes. In lakes that thermally stratify, internal phosphorus release can occur from the sediment through chemical means. Once oxygen is depleted (anoxia) in the hypolimnion, chemical reactions occur in which phosphorus bound to iron complexes in the sediment becomes soluble and is released into the water column. This phosphorus is trapped in the hypolimnion and is unavailable to algae until fall turnover, and can cause algae blooms once

it moves into the sunlit surface water at that time. Accordingly, many of the lakes in Lake County are plagued by dense algae blooms and excessive, exotic plant coverage, which negatively affect DO levels, fish communities and water clarity.

Lakes with an average phosphorus concentration greater than 0.05 mg/L are considered nutrient rich. The median near surface total phosphorus (TP) concentration in Lake County lakes from 2000-2005 is 0.063 mg/L and ranged from a non-detectable minimum of <0.010 mg/L on five lakes to a maximum of 3.880 mg/L on Albert Lake. The median anoxic TP concentration in Lake County lakes from 2000-2005 was 0.174 mg/L and ranged from a minimum of 0.012 mg/L in West Loon Lake to a maximum of 3.880 mg/L in Taylor Lake.

The analysis of phosphorus also included soluble reactive phosphorus (SRP), a dissolved form of phosphorus that is readily available for plant and algae growth. SRP is not discussed in great detail in most of the water quality reports because SRP concentrations vary throughout the season depending on how plants and algae absorb and release it. It gives an indication of how much phosphorus is available for uptake, but, because it does not take all forms of phosphorus into account, it does not indicate how much phosphorus is truly present in the water column. TP is considered a better indicator of a lake's nutrient status because its concentrations remain more stable than soluble reactive phosphorus. However, elevated SRP levels are a strong indicator of nutrient problems in a lake.

Nitrogen:

Nitrogen is also an important nutrient for plant and algae growth. Sources of nitrogen to a lake vary widely, ranging from fertilizer and animal wastes, to human waste from sewage treatment plants or failing septic systems, to groundwater, air and rainfall. As a result, it is very difficult to control or reduce nitrogen inputs to a lake. Different forms of nitrogen are present in a lake under different oxic conditions. NH₄⁺ (ammonium) is released from decomposing organic material under anoxic conditions and accumulates in the hypolimnion of thermally stratified lakes. If NH₄⁺ comes into contact with oxygen, it is immediately converted to NO₂ (nitrite) which is then oxidized to NO₃⁻ (nitrate). Therefore, in a thermally stratified lake, levels of NH₄⁺ would only be elevated in the hypolimnion and levels of NO₃ would only be elevated in the epilimnion. Both NH₄⁺ and NO₃⁻ can be used as a nitrogen source by aquatic plants and algae. Total Kjeldahl nitrogen (TKN) is a measure of organic nitrogen plus ammonium. Adding the concentrations of TKN and nitrate together gives an indication of the amount of total nitrogen present in the water column. If inorganic nitrogen (NO₃, NO₂, NH₄⁺) concentrations exceed 0.3 mg/L in spring, sufficient nitrogen is available to support summer algae blooms. However, low nitrogen levels do not guarantee limited algae growth the way low phosphorus levels do. Nitrogen gas in the air can dissolve in lake water and blue-green algae can "fix" atmospheric nitrogen, converting it into a usable form. Since other types of algae do not have the ability to do this, nuisance blue-green algae blooms are typically associated with lakes that are nitrogen limited (i.e., have low nitrogen levels).

The ratio of TKN plus nitrate nitrogen to total phosphorus (TN:TP) can indicate whether plant/algae growth in a lake is limited by nitrogen or phosphorus. Ratios of less than 10:1

suggest a system limited by nitrogen, while lakes with ratios greater than 20:1 are limited by phosphorus. It is important to know if a lake is limited by nitrogen or phosphorus because any addition of the limiting nutrient to the lake will, likely, result in algae blooms or an increase in plant density.

Solids:

Although several forms of solids (total solids, total suspended solids, total volatile solids, total dissolved solids) were measured each month by the Lakes Management Staff, total suspended solids (TSS) and total volatile solids (TVS) have the most impact on other variables and on the lake as a whole. TSS are particles of algae or sediment suspended in the water column. High TSS concentrations can result from algae blooms, sediment resuspension, and/or the inflow of turbid water, and are typically associated with low water clarity and high phosphorus concentrations in many lakes in Lake County. Low water clarity and high phosphorus concentrations, in turn, exacerbate the high TSS problem by leading to reduced plant density (which stabilize lake sediment) and increased occurrence of algae blooms. The median TSS value in epilimnetic waters in Lake County is 7.9 mg/L, ranging from below the 1 mg/L detection limit (10 lakes) to 165 mg/L in Fairfield Marsh.

TVS represents the fraction of total solids that are organic in nature, such as algae cells, tiny pieces of plant material, and/or tiny animals (zooplankton) in the water column. High TVS values indicate that a large portion of the suspended solids may be made up of algae cells. This is important in determining possible sources of phosphorus to a lake. If much of the suspended material in the water column is determined to be resuspended sediment that is releasing phosphorus, this problem would be addressed differently than if the suspended material was made up of algae cells that were releasing phosphorus. The median TVS value was 132 mg/L, ranging from 34 mg/L in Pulaski Pond to 298 mg/L in Fairfield Marsh.

Total dissolved solids (TDS) are the amount of dissolved substances, such as salts or minerals, remaining in water after evaporation. These dissolved solids are discussed in further detail in the *Alkalinity* and *Conductivity* sections of this document. TDS concentrations were measured in Lake County lakes prior to 2004, but was discontinued due to the strong correlation of TDS to conductivity and chloride concentrations.

Water Clarity:

Water clarity (transparency) is not a chemical property of lake water, but is often an indicator of a lake's overall water quality. It is affected by a lake's water color, which is a reflection of the amount of total suspended solids and dissolved organic chemicals. Thus, transparency is a measure of particle concentration and is measured with a Secchi disk. Generally, the lower the clarity or Secchi depth, the poorer the water quality. A decrease in Secchi depth during the summer occurs as the result of an increase in suspended solids (algae or sediment) in the water column. Aquatic plants play an important role in the level of water clarity and can, in turn, be negatively affected by low clarity levels. Plants increase clarity by competing with algae for

resources and by stabilizing sediments to prevent sediment resuspension. A lake with a healthy plant community will almost always have higher water clarity than a lake without plants. Additionally, if the plants in a lake are removed (through herbicide treatment or the stocking of grass carp), the lake will probably become dominated by algae and Secchi depth will decrease. This makes it very difficult for plants to become re-established due to the lack of available sunlight and the lake will, most likely, remain turbid. Turbidity will be accelerated if the lake is very shallow and/or common carp are present. Shallow lakes are more susceptible to sediment resuspension through wind/wave action and are more likely to experience clarity problems if plants are not present to stabilize bottom sediment.

Common Carp are prolific fish that feed on invertebrates in the sediment. Their feeding activities stir up bottom sediment and can dramatically decrease water clarity in shallow lakes. As mentioned above, lakes with low water clarity are, generally, considered to have poor water quality. This is because the causes and effects of low clarity negatively impact the plant and fish communities, as well as the levels of phosphorus in a lake. The detrimental impacts of low Secchi depth to plants has already been discussed. Fish populations will suffer as water clarity decreases due to a lack of food and decreased ability to successfully hunt for prev. Bluegills are planktivorous fish and feed on invertebrates that inhabit aquatic plants. If low clarity results in the disappearance of plants, this food source will disappear too. Largemouth Bass and Northern Pike are piscivorous fish that feed on other fish and hunt by sight. As the water clarity decreases, these fish species find it more difficult to see and ambush prey and may decline in size as a result. This could eventually lead to an imbalance in the fish community. Phosphorus release from resuspended sediment could increase as water clarity and plant density decrease. This would then result in increased algae blooms, further reducing Secchi depth and aggravating all problems just discussed. The average Secchi depth for Lake County lakes is 3.17 feet. From 2000-2005, Fairfield Marsh and Patski Pond had the lowest Secchi depths (0.33 feet) and Bangs Lake had the highest (29.23 feet). As an example of the difference in Secchi depth based on plant coverage, South Churchill Lake, which had no plant coverage and large numbers of Common Carp in 2003 had an average Secchi depth of 0.73 feet (over four times lower than the county average), while Deep Lake, which had a diverse plant community and few carp had an average 2003 Secchi depth of 12.48 feet (almost four times higher than the county average).

Another measure of clarity is the use of a light meter. The light meter measures the amount of light at the surface of the lake and the amount of light at each depth in the water column. The amount of attenuation and absorption (decreases) of light by the water column are major factors controlling temperature and potential photosynthesis. Light intensity at the lake surface varies seasonally and with cloud cover, and decreases with depth. The deeper into the water column light penetrates, the deeper potential plant growth. The maximum depth at which algae and plants can grow underwater is usually at the depth where the amount of light available is reduced to 0.5%-1% of the amount of light available at the lake surface. This is called the euphotic (sunlit) zone. A general rule of thumb in Lake County is that the 1% light level is about 1 to 3 times the Secchi disk depth.

Alkalinity, Conductivity, Chloride, pH:

Alkalinity:

Alkalinity is the measurement of the amount of acid necessary to neutralize carbonate (CO₃⁻) and bicarbonate (HCO₃⁻) ions in the water, and represents the buffering capacity of a body of water. The alkalinity of lake water depends on the types of minerals in the surrounding soils and in the bedrock. It also depends on how often the lake water comes in contact with these minerals. If a lake gets groundwater from aquifers containing limestone minerals such as calcium carbonate (CaCO₃) or dolomite (CaMgCO₃), alkalinity will be high. The median alkalinity in Lake County lakes (162 mg/L) is considered moderately hard according to the hardness classification scale of Brown, Skougstad and Fishman (1970). Because hard water (alkaline) lakes often have watersheds with fertile soils that add nutrients to the water, they usually produce more fish and aquatic plants than soft water lakes. Since the majority of Lake County lakes have a high alkalinity they are able to buffer the adverse effects of acid rain.

Conductivity and Chloride:

Conductivity is the inverse measure of the resistance of lake water to an electric flow. This means that the higher the conductivity, the more easily an electric current is able to flow through water. Since electric currents travel along ions in water, the more chemical ions or dissolved salts a body of water contains, the higher the conductivity will be. Accordingly, conductivity has been correlated to total dissolved solids and chloride ions. The amount of dissolved solids or conductivity of a lake is dependent on the lake and watershed geology, the size of the watershed flowing into the lake, the land uses within that watershed, and evaporation and bacterial activity. Many Lake County lakes have elevated conductivity levels in May, but not during any other month. This was because chloride, in the form of road salt, was washing into the lakes with spring rains, increasing conductivity. Most road salt is sodium chloride, calcium chloride, potassium chloride, magnesium chloride or ferrocyanide salts. Beginning in 2004, chloride concentrations are one of the parameters measured during the lake studies. Increased chloride concentrations may have a negative impact on aquatic organisms. Conductivity changes occur seasonally and with depth. For example, in stratified lakes the conductivity normally increases in the hypolimnion as bacterial decomposition converts organic materials to bicarbonate and carbonate ions depending on the pH of the water. These newly created ions increase the conductivity and total dissolved solids. Over the long term, conductivity is a good indicator of potential watershed or lake problems if an increasing trend is noted over a period of years. It is also important to know the conductivity of the water when fishery assessments are conducted, as electroshocking requires a high enough conductivity to properly stun the fish, but not too high as to cause injury or death.

pH:

pH is the measurement of hydrogen ion (H⁺) activity in water. The pH of pure water is neutral at 7 and is considered acidic at levels below 7 and basic at levels above 7. Low pH levels of 4-5 are toxic to most aquatic life, while high pH levels (9-10) are not only toxic to aquatic life but may also result in the release of phosphorus from lake sediment. The presence of high plant densities can increase pH levels through photosynthesis, and lakes dominated by a large amount of plants or algae can experience large fluctuations in pH levels from day to night, depending on the rates of photosynthesis and respiration. Few, if any pH problems exist in Lake County lakes. Typically, the flooded gravel mines in the county are more acidic than the glacial lakes as they have less biological activity, but do not usually drop below pH levels of 7. The median near surface pH value of Lake County lakes is 8.30, with a minimum of 7.06 in Deer Lake and a maximum of 10.28 in Round Lake Marsh North

Eutrophication and Trophic State Index:

The word *eutrophication* comes from a Greek word meaning "well nourished." This also describes the process in which a lake becomes enriched with nutrients. Over time, this is a lake's natural aging process, as it slowly fills in with eroded materials from the surrounding watershed and with decaying plants. If no human impacts disturb the watershed or the lake, natural eutrophication can take thousands of years. However, human activities on a lake or in the watershed accelerate this process by resulting in rapid soil erosion and heavy phosphorus inputs. This accelerated aging process on a lake is referred to as cultural eutrophication. The term trophic state refers to the amount of nutrient enrichment within a lake system. Oligotrophic lakes are usually deep and clear with low nutrient levels, little plant growth and a limited fishery. Mesotrophic lakes are more biologically productive than oligotrophic lakes and have moderate nutrient levels and more plant growth. A lake labeled as *eutrophic* is high in nutrients and can support high plant densities and large fish populations. Water clarity is typically poorer than oligotrophic or mesotrophic lakes and dissolved oxygen problems may be present. A hypereutrophic lake has excessive nutrients, resulting in nuisance plant or algae growth. These lakes are often pea-soup green, with poor water clarity. Low dissolved oxygen may also be a problem, with fish kills occurring in shallow, hypereutrophic lakes more often than less enriched lakes. As a result, rough fish (tolerant of low dissolved oxygen levels) dominate the fish community of many hypereutrophic lakes. The categorization of a lake into a certain trophic state should not be viewed as a "good to bad" categorization, as most lake residents rate their lake based on desired usage. For example, a fisherman would consider a plant-dominated, clear lake to be desirable, while a water-skier might prefer a turbid lake devoid of plants. Most lakes in Lake County are eutrophic or hypereutrophic. This is primarily as a result of cultural eutrophication. However, due to the fertile soil in this area, many lakes (especially man-made) may have started out under eutrophic conditions and will never attain even mesotrophic conditions, regardless of any amount of money put into the management options. This is not an excuse to allow a lake to continue to deteriorate, but may serve as a reality check for lake owners attempting to create unrealistic conditions in their lakes.

The Trophic State Index (TSI) is an index which attaches a score to a lake based on its average

total phosphorus concentration, its average Secchi depth (water transparency) and/or its average chlorophyll *a* concentration (which represent algae biomass). It is based on the principle that as phosphorus levels increase, chlorophyll *a* concentrations increase and Secchi depth decreases. The higher the TSI score, the more nutrient-rich a lake is, and once a score is obtained, the lake can then be designated as oligotrophic, mesotrophic or eutrophic. Table 1 (below) illustrates the Trophic State Index using phosphorus concentration and Secchi depth.

Table 1. Trophic State Index (TSI).

Trophic State	TSI score	Total Phosphorus (mg/L)	Secchi Depth (feet)
Oligotrophic	<40	≤ 0.012	>13.12
Mesotrophic	≥40<50	>0.012 \le 0.024	≥6.56<13.12
Eutrophic	≥50<70	$>0.024 \le 0.096$	≥1.64<6.56
Hypereutrophic	≥70	>0.096	< 1.64
